Particle-in-cell (PIC) methods have been widely used for solving the gyrokinetic equations
and simulating turbulence in tokamak and stellarator. Most of the existing PIC codes are based
on the $\delta f$ method [1]. The distribution function $f$ of each plasma species can be split into a
time independent background distribution function $f_0$ and a time dependent perturbation $\delta f$,
$f = f_0 + \delta f$. In the $\delta f$ method, the perturbed part only ($\delta f$) is discretised using numerical
particles, also called markers. As long as the perturbation $\delta f$ keeps small as compared to $f_0$,
the $\delta f$ method reduces the statistical noise. The $\delta f$ method can be interpreted as a "control
variates" algorithm [2, 3], a variance reduction technique widely used in Monte Carlo methods.

Many linear and nonlinear global gyrokinetic $\delta f$ PIC codes exist and are routinely used for
simulating electrostatic perturbations. However, the electrostatic approximation is expected to
break down in the core of high $\beta_e$ ($\beta_e \equiv n_eT_e/B^2$) plasmas or in any region where pressure gra-
dients are large. For a finite value of $\beta_e$, magnetic fluctuations modify the evolution of the elec-
trostatic instabilities and eventually introduce new electromagnetic modes [4]. Electromagnetic
simulations using a conventional $\delta f$ method are much more demanding in respect of numerical
resources than electrostatic simulations. In particular, the parallel electron dynamics imposes a
strong constraint on the size of the time step. In addition to this, electromagnetic simulations
require a much larger number of numerical particles in order to correctly describe the evolution
of the nonadiabatic part of the electron distribution function. Indeed, the physically relevant
nonadiabatic part of the electron distribution function is overwhelmed by the adiabatic response
to the magnetic potential $A_\|$, leading to a severe accuracy problem, known in the literature as
"cancellation problem" (see [3] and references therein). An accurate enough description of this
small signal requires a very low statistical noise or, in other words, a huge number of numerical
particles.

The code used in this work is the global $\delta f$ PIC code ORB5 [5]. ORB5 solves the set of
gyrokinetic equations in the whole plasma core down to the magnetic axis. The use of MHD
equilibria leads to a totally consistent inclusion of geometrical parameters such as the Shafranov
shift and allows for simulating most of the existing tokamak experiments and future reactor
size machines. A field-aligned filtering procedure and sophisticated noise-control and heating operators allow for accurate simulations with smaller numbers of markers than standard $\delta f$ PIC simulations [6]. The code ORB5 has been proved to scale up to 32k cores on a BlueGene-P architecture. The strong scaling for the standard ITM CYCLONE base-case, described in Ref. [4], is shown in Fig. 1.

The code ORB5 has been extended to include magnetic perturbations in $A_{\parallel}$. Ampère’s law, as well as the Poisson equation, are discretised with finite elements (B-splines). The cancellation problem of the unphysical adiabatic currents is solved using an adjustable control variates method. The control variate, in this case, correspond to the part of the distribution function of the electrons responding adiabatically to the magnetic potential $A_{\parallel}$.

This scheme is described in detail in Section 8.2 of Ref. [3]. Note that the same scheme has been successfully applied in linear PIC simulations in tokamak geometry [7]. The gyrokinetic model implemented in ORB5 is derived from the Vlasov-Poisson-Ampère model of Ref. [8], in the $p_{\parallel}$ formulation. The code ORB5 solves the following Ampère’s law:

$$ C_A \left( \frac{\beta_i}{\rho_{i}^2} + \frac{\beta_e}{\rho_{e}^2} \right) A_{\parallel} - \nabla^2 A_{\parallel} = \mu_0 \left( j_{\parallel,i} + j_{\parallel,e} \right) $$

(1)

where $j_{\parallel,s}$ is the gyrocenter current, $\rho_s$ is the thermal gyroradius and $\beta_s \equiv \mu_0 n_0 T_s / B_0^2$ of the species $s$. The first two terms $\propto \beta_s / \rho_s^2$ on the left-hand side of Eq. (1) are the ion and electron skin terms which exactly cancel the adiabatic part of currents on the right-hand side. The $C_A$ factor in front of the skin terms is due to the finite extent of the velocity-space domain in the simulations. The value of $C_A$ is close to unity and varies with the radius. The inclusion of this factor is crucial for the correct solution of the cancellation problem as it was shown in Ref. [9]. The electromagnetic version of ORB5 has been tested in simpler geometry and benchmarked against the linear electromagnetic code GYGLES (see Ref. [7] and referenced therein) in tokamak geometry. For this benchmark we have considered a circular equilibrium with major radius $R_0 = 2.0$ m, minor radius $a = 0.5$ m and $\rho^* = 1/110$ at mid-radius. The value of the density on the axis has been varied in the simulations in order to perform a scan in

\( \beta_e \). Details about the equilibrium profiles can be found in Ref. [7]. The two codes are in good agreement in both growth rates and real frequencies. For the case \( \beta_e = 1\% \) the dominant mode is still an ion temperature gradient driven (ITG) mode partially stabilized by finite \( \beta_e \) effects. For \( \beta_e > 2\% \) the most unstable mode is clearly an electromagnetic kinetic ballooning mode (KBM) (see Fig. 2). Figure 2 (bottom) shows the poloidal cross section of the potentials for the \( \beta_e = 2\% \) case. All the ORB5 linear simulations were performed with 128 m ion markers and 256 m electron markers.

The nonlinear simulations of Fig. 3 are based on parameters and profiles of the ITM Cyclone base case described in Ref. [4]. The mass ratio is \( m_i/m_e = 1000 \) and the value of the central density has been adjusted to have \( \beta_e = 0.3\% \). Note that in these simulations (as well as in Ref. [4]) no heat sources are applied, the initial temperature gradient \((R/L_T \simeq 9)\) relaxes during the time evolution toward the critical gradient value. The EM simulation was performed using 512 million numerical particles per species and with a time step 20 times smaller as compared to the electrostatic case \((\Delta t = 1/\Omega_{c,i})\) where \( \Omega_{c,i} \) is the ion cyclotron frequency). The ion thermal
diffusivity is clearly larger in the $\beta_e = 0.3\%$ case as compared to the electrostatic case due to the trapped electron contribution to the ITG instability. This effect is obviously not present in all the simulations of Ref. [4] were adiabatic electrons were used.

A more detailed analysis of the heat fluxes shows that the magnetic flutter terms are negligible and do not affect ions, in agreement with existing flux-tube results [10]. During the simulation the signal/noise diagnostics [11] show a noise/signal ratio ranging between 5% and 10%.

The inclusion of Ampère’s law does not degrade the scaling properties of ORB5, since the field solver time is a small fraction of the total computational time. The first nonlinear simulations show that a high radial resolution is required for describing the nonadiabatic electron dynamics in the vicinity of resonant surfaces. When the radial resolution is too poor spurious modes appear in electromagnetic simulations [12]. In general, achievement of converged global nonlinear electromagnetic simulations requires a large amount of numerical resources due to the constraints imposed by Alfvén dynamics and the kinetic electrons. Indeed, electromagnetic simulations of the Cyclone base case for $\beta_e > 0.3\%$ seem to require even higher number of markers than the case presented in this work.
