Introduction

In future experimental nuclear fusion reactors, power exhaust handling and plasma wall interaction must be controlled to a level compatible with wall materials. Tokamak operation will thus feature highly radiative edges. However, radiation in the core plasma must be minimized to preserve the energy content.

Many solutions have been proposed to reduce the plasma-wall interaction by acting on the magnetic field topology in diverted plasmas [2–5]. One of these solutions is the so-called snowflake (SF) divertor [2, 3]. The basic concept of the snowflake divertor (SF) is illustrated in Fig. 1.

In a standard X-point configuration (not shown here) the poloidal magnetic field vanishes at the X-point (first order null). An SF diverted configuration is characterized by a second order null, i.e. the first derivatives of the magnetic field also vanish at the null point and the separatrix divides the poloidal plane into six sectors, Fig. 1(b). Perturbing the exact SF configuration produces the magnetic configurations which are respectively shown in Fig. 1(a) and Fig. 1(c). In these two configurations, the first derivatives of the poloidal magnetic field are small compared to those of a standard X-point (single null configuration, SN). Following Ref. [2, 3], we will refer to these two configurations as of snowflake-plus (SF+) and snowflake-minus (SF-) respectively.

Figure 1: SF configurations in a straight tokamak model. The circles represent the current filaments (plasma, \(I_p\), and divertor conductors, \(I_{d1,2}\)) and the bold black line is the separatrix.
The second order null modifies the magnetic topology near the plasma boundary and is therefore expected to affect the plasma properties in the scrape-off layer (SOL). The magnetic shear at the edge, where the pedestal lies is also modified, and may influence Edge Localized Modes (ELMs) activity in H-modes. Squeezing the flux tubes near the null point may also decouple the turbulence in the divertor legs and in the SOL and change the radial blob motion.

SF experiments on TCV

All three SF configurations have been created and controlled on the TCV tokamak [6], as shown in Fig. 2, demonstrating the feasibility of such plasmas.

Although the CCD images in fig. 2 are saturated, the visible emission qualitatively confirms the SF configurations reproduced by the magnetic reconstruction code.

The magnetic properties of the SF configurations are compared with those of the SN configuration using the magnetic measurements from the equilibria in Fig. 2.

For the SOL, an important parameter is the flux expansion. This quantity is related to the reduction of the poloidal magnetic field near the null point. The flux expansion influences the SOL thickness and the size of the radiating volume. Radial transport, and possible filaments in the edge/SOL region, may also be influenced. For a given flux surface, the flux expansion is defined as the ratio \( \psi_{\text{exp}} = \frac{\Delta}{R - R_{\text{sep}}} \), where \( \Delta \) is the minimum distance between the X-point and the considered magnetic field line, and \( R - R_{\text{sep}} \) is the distance between the same field line and the separatrix at the outer midplane.

In Fig. 3, the flux expansion for the SF configurations and for the SN configuration are plotted as a function of the distance \( R - R_{\text{sep}} \). The connection length from the equatorial plane to the point closest to the x-point (CLx) is also shown. The connection length determines the residence time of a particle in the SOL and therefore affects the radiative losses and the thermal power to the divertor plates (the thickness of the SOL at the outer midplane is typically \( \sim 2 \text{ cm} \)).
SF configuration has a flux expansion near the separatrix (Near SOL) and a connection length over two times larger than that for the equivalent SN. The SF+ and the SF- have similar values of flux expansion and connection length, with values that fall between the values computed for the SF configuration and the SN configuration.

The safety factor profile ($q$) and the magnetic shear ($s = \frac{\rho_{\text{vol}}}{q} \frac{dq}{d\rho_{\text{vol}}}$) are computed using the CHEASE code [7] and are also shown in Fig. 3. The LCFS used to compute these quantities ($\rho_{\text{vol}} = 1$) is just inside the separatrix to avoid the singularity of $q$ and $s$ at the null point. The SF configuration has a larger magnetic shear than that for the SN configuration. This difference is large for $\rho_{\text{vol}} > 0.96$. The SF+ and the SF- configurations also exhibit larger magnetic shear compared to the SN configuration. In the case of the SF- configuration, the presence of a double null in the separatrix results in a large volume where the poloidal magnetic field is small. This property emphasizes a dissimilarity in the magnetic shear profile compared with the SF+ configuration. Note that the profiles of the SF- are very similar to the SF up to $\rho_{\text{vol}} \approx 0.985$ but then become closer to the SF+ and the SN. This may lead to differences in the MHD stability limits in between the SF+ and SF- which will be investigated in the future.

**H-mode experiments in an SF configuration**

The MHD stability limits of the SF configuration were computed and compared to those of a SN configuration [8, 9]. It was found that the SF configuration does not degrade edge MHD stability and that the current driven kink modes of medium $n$ are predicted to be more stable.
compared to the SN configuration.

Figure 4: Electron plasma density ($n_e$), H$_\alpha$ and C-III radiation and soft-X radiation ($DMPX$ signal) during an H-mode in both an SN and an SF configurations.

More experiments are planned to investigate the H-mode accessibility and the pedestal stability in H-mode SF configurations.

Starting from these theoretical results, an experimental campaign on TCV was undertaken to verify the accessibility of the H-mode with SF configurations.

In fig. 4, the electron plasma density $n_e$, the H$_\alpha$ and the C-III radiation and the soft-X radiation is plotted for an ohmic plasma discharge. During this experiment, the plasma configuration is modified; starting from a limited plasma, a SN configuration is created at $t = 0.31\, s$ and finally at $t = 0.62\, s$ the SF+ configuration is achieved. In spite of the small input power ($I_P = 300\, kA, P_{in} \sim 400\, kW$), an ELMy H-mode regime is observed in both the SN configuration and the SF configuration.
